ABSTRACT

An ammonia absorption spectrum recorded at room temperature in the region 8800–10,400 cm $^{-1}$ is analysed using a variational line list, BYTe, and ground state energies determined using the MARVEL procedure. BYTe is used as a starting point to initialise assignments by combination differences and the method of branches. Assignments are presented for the region 9400–9850 cm $^{-1}$. 642 lines are assigned to 6 previously unobserved vibrational bands, $(2v_1 + 2v_4^2)^{\pm}$, $(2v_1 + v_3^1)^{\pm}$ and $(v_1 + v_3^1 + 2v_4^2)^{\pm}$, leading to 428 new energy levels with 208 confirmed by combination differences. A recently calculated purely *ab initio* NH₃ PES is also used to calculate rovibrational energy levels. Comparison with assigned levels shows better agreement between observed and calculated levels than for BYTe for higher vibrational bands.

1. Introduction

Ammonia is an atmospheric trace species which is frequently the by-product of human activity [1]. Ammonia is present in a variety of astronomical environments, including the interstellar medium, gas giant planets [2] and brown dwarfs [3]; indeed NH₃ is thought to provide the signature of coolest brown dwarfs known as Y-dwarfs [4]. NH₃ is also used in a number of industrial processes, such as the reduction of NOx emissions in smoke stacks [5] and the manufacture of hydrogen cyanide by the Andrussow process [6]. This has motivated a large number of experimental studies of ammonia spectra; those reported up to late 2014 are reviewed in the MARVEL (measured active rotation-vibration energy levels) study of NH₃ performed by Al-Derzi et al. [7], which is discussed further below.

A number of new ammonia spectra have been reported in the last two years [8–14]. Of particular relevance to this work is the analysis by Barton et al. [12] of a near-infrared Fourier transform spectrum which was originally recorded by Dr Catherine de Bergh in 1980 at Kitt Peak. Barton et al. used a combination of the BYTe

variational line list of Yurchenko, Barber and Tennyson [15], energy levels from the MARVEL study, and the method of branches [16] to assign 2474 lines in the 7400–8600 cm⁻¹region; this is the first time any assignments had been made for ammonia spectra in this region.

The success of this work, and the availability of unassigned, shorter-wavelength ammonia spectra in the Kitt Peak archive and from elsewhere (see below) motivated us to attempt to extend the analysis techniques employed by Barton et al. [12] to higher wavenumbers. The results of this analysis are reported here. We note that the 2012 release of HITRAN contained no data on NH₃ above 7000 cm⁻¹.

One reason for extending the range of assigned NH₃ spectra is to help the construction of accurate potential energy surfaces (PES). Quite a number of PES are available for the ground states of NH₃. The majority of these are the products of *ab initio* electronic structure calculations [17–23], although surfaces that use experimental data to improve their accuracy are also available [24–26]. Recently, Polyansky et al. [23] computed an *ab initio* surface with which they were able to make, for the first time, vibrational assignments to the optical spectrum of ammonia recorded by Coy and Lehmann [27,28]. We consider results obtained with this PES further below.

2. Experimental data

The Kitt Peak data center provides open access to laboratory Fourier Transform (FT) spectra recorded at the National Solar Observatory. The room temperature laboratory absorption spectrum of NH₃ analysed here was recorded by Dr. Catherine de Bergh using a one meter FT spectrometer in 1980 and corresponds to FITS file 800407R0.003 in the Kitt Peak archive. The spectrometer in question was a permanent instrument on the McMath Solar Telescope and was used for both solar and laboratory analysis.

A summary of information provided by the header of the archive file is presented in Table 1 and an overview of the raw spectrum is given in Fig. 1. Absorption lines were detected between 8800 and 10.400 cm⁻¹.

The wavenumber scale was calibrated using water lines which are clearly apparent between 8800 and 9000 cm $^{-1}$. A few additional water lines are also detected near the high energy limit at 10200 cm $^{-1}$. On the basis of the HITRAN list for water vapor, 113 lines were identified as water lines using an automatic search program taking into account both positions and line intensities. Their positions were used for frequency calibration of the spectrum. A correction factor of 0.99999625(4) was determined and applied to the frequency scale (the frequency correction is about $-0.035~{\rm cm}^{-1}$ at $9000~{\rm cm}^{-1}$).

Line centers and line intensities were systematically retrieved using a multiline fitting of the spectrum based on a homemade three step suite of programs written in Labview and C++. An effective Voigt profile, including the contribution of the apparatus function, was first determined from a small number of isolated lines and used as default profile. Then an automatic multiline fit was performed over the entire analysed region by adjusting only the line center and integrated line absorbance, the shape of all the lines being fixed to the default Voigt profile. Finally, a manual adjustment was performed by further refining the profile parameters and adding/deleting weak lines (see more details in Ref. [12]). The quality with which the spectrum is reproduced is illustrated in Fig. 2.

Overall a list of more than 12,900 lines was obtained. After exclusion of the lines due to water vapor and of the weak lines with intensities below 10^{-25} cm/molecule, a list of 12064 lines of ammonia lying between 8978 and 10,348 cm⁻¹ was considered for ro-vibrational assignment. This line list given in the supplementary data is presented in Fig. 3. Of importance for the search for combination differences is the fact that the accuracy of the line centers is believed to be better than 0.005 cm⁻¹ for non-blended lines as the rms deviation of the position of the 113 water lines used for calibration is 0.0038 cm⁻¹. The average uncertainty on the retrieved line intensities is estimated to be about 15% for isolated lines of intermediate intensity.

In parallel, new spectra were recorded at the Academy of Science of the Czech Republic in Prague. FTIR spectra were measured in a 50 m long optical White cell equipped with CaF_2 windows. The cell was interfaced to a sealable glass-tube joint for the transfer of the ammonia gas from a side ampule. The optical cell

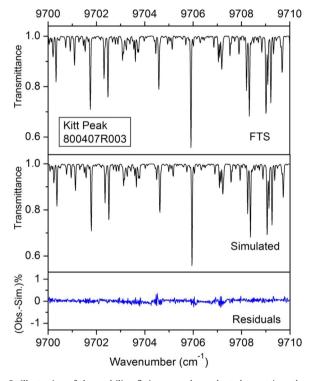

Fig. 2. Illustration of the multiline fitting procedure adopted to retrieve the ammonia line parameters. The FTS spectrum (800407R0.003) was recorded by C. de Bergh and corresponds to a 25 m pathlength and a 5 Torr pressure.

was further equipped with a second vacuum valve (ACE glass, USA) for the gas handling and connection to the vacuum line. The pressure in the measuring cell was 2 Torr, measured with a MKS Baratron pressure gauge (0–10 Torr pressure range). The spectral measurement was performed using the Bruker IFS 125 HR spectrometer (CaF₂ beam splitter, InSb detector) in a spectral range of 1800–10,000 cm⁻¹. The spectra were measured in the gas phase with a resolution of 0.01 cm⁻¹ with 100 scans using the Blackmann-Harris apodization function. This spectrum was helpful for confirming calibration but yielded few lines above 9000 cm⁻¹ so is not considered further here.

3. Data analysis

Our procedure for making line assignments followed closely our previous analysis of a near infrared Kitt Peak spectrum [12]. E.J. Barton et al. / Journal of Quantitative Spectroscopy & Radiative Transfer ■ (■■■) ■■■-■■■

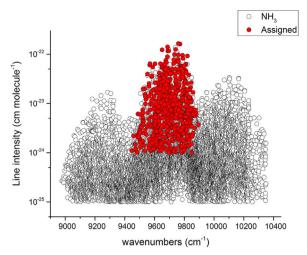

Fig. 3. Overview of the NH₃ line list for the region 9000-10,400 cm⁻¹ retrieved from the Kitt Peak archive. Fully assigned lines are in filled circles, unassigned lines are open circles.

Data analysis relied on the use of MARVEL data and the BYTe variational line list [15]. A number of variational line lists are available for NH_3 [15,29,30] but BYTe, which was designed to be used up to $12,000 \, \text{cm}^{-1}$, is the only one which really extends above $9000 \, \text{cm}^{-1}$.

The MARVEL algorithm [31,32] is designed to invert all available assigned and labelled experimental lines, to give accurate empirical energy levels. Although the recent NH₃ MARVEL analysis of Al-Derzi et al. [7] included transitions up to 17,000 cm⁻¹, there was a gap between 7000 and 15,000 cm⁻¹ due to absence of any assigned NH₃ lines in this region.

A list of observable BYTe lines for the experimental conditions was generated. This list included all lines with an absorption intensity greater that 1×10^{-25} cm/molecule at 296 K. In the 9400–9850 cm $^{-1}$ region, this list contains 11 251 lines of which 151 are stronger than 3×10^{-23} cm/molecule which can be compared to the observations which contain 5776 and 150 lines, respectively, in this region for the given intensity cut-offs.

BYTe is expected to be fairly complete in the region of interest but not particularly accurate as BYTe is known to be less accurate for higher wavenumber transitions [25,30,33,12]. In particular our previous study of the 7400–8600 cm⁻¹ region found that BYTe predictions differed by between –2 and +3 cm⁻¹ from the observed transition wavenumbers. In this work we only considered transitions which lay within 5 cm⁻¹ of the BYTe predictions. Given that the BYTe predictions are expected to deteriorate to higher wavenumbers, this limit may well have precluded some matches.

Fig. 4 compares the Kitt Peak spectrum with the predictions of the BYTe line list. The overview comparison given in the upper part of the figure shows very good overall agreement between the two spectra, albeit with some variation between the observed and computed intensities. However, the more detailed comparison given below shows that there are significant shifts between the line position predicted by BYTe and the observed ones.

We used the confirmed combination differences of the assigned levels to assess the BYTe predictions via the observed minus calculated (Obs. - Calc.) differences provided by the lines assigned using combination differences. For a given vibrational band, these (Obs. - Calc.) differences are normally systematic within a given vibrational band enabling us to use the method of branches [16], which exploits the systematic shifts of variational predictions within any one vibration band, to make further assignments. Lines assigned by this method are generally not confirmed by combination differences because the other transitions associated with the upper level

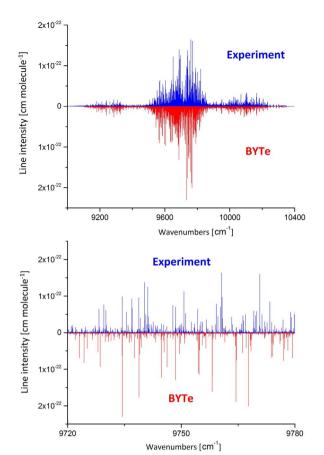

Fig. 4. Comparison of the NH₃spectrum between the Kitt Peak measurements (Experiment) and the predictions of the BYTe line list. The upper panel gives an overview of the entire 9000-10,400cm⁻¹ spectral region while the lower panel gives a more detailed comparison.

either lie outside the spectral range considered or are too weak to be included in experimental line list. However, the ratio between observed and calculated intensities was used as additional check on these assignments. If these intensities differed by more than a factor of two then the tentative assignment was rejected.

4. Results and discussion

A full list of lines obtained from the Kitt Peak spectrum is given in the supplementary information. The line assignments given use the full recommended quantum number set of Down et al. [34] and are labelled according to whether the assignments are based on combination differences or branch assignments. Table 2 and 3 gives a sample set of each type of assignment.

The final assignment list is a compilation of all combination difference (CD) and branch (Br) assignments. Our assignments are confined to the 9400–9850 cm⁻¹ region which contains the strongest bands. We did obtain some potential matches outside this region but, due to the inaccuracy of BYTe at these frequencies and lower intensity of the observed spectra leading to fewer combination differences, we could not be confident that our tentative assignments are correct. Analysis of transitions outside this region is therefore left for future work.

Table 4 summarizes the number of lines assigned for each of six bands analyzed and gives a breakdown between combination difference and branch assignments. A total of 642 lines are assigned, the majority of these are confirmed by combination differences. All assigned transitions are for overtone bands, i.e. involve absorption by the 0[±] lower vibrational state.

Table 2 A sample of the assigned transitions confirmed by combination differences. Abbreviated $(v_1v_2v_2^{J_3}v_4^{L_4})^i$ vibrational labels followed by rotational quantum numbers J and K are given below, full quantum assignments are provided in the supplementary data.

spectrum of NH₃ [23]. The predictions reproduce the observed band origins with a standard deviation of $3.6 \, \mathrm{cm}^{-1}(\mathrm{BYTe})$ and $2.2 \, \mathrm{cm}^{-1}(ab \, initio)$. Given that the PES used in the BYTe calculations was determined using a considerable number of spectroscopic data it is interesting to note that the *ab initio* predictions are somewhat closer to the observations for the region studied here. We note that other bands, such as $(v_1 + 2v_2 + 2v_4^2)^-$, $(2v_2 + 2v_4^0)^\pm$ and $(v_1 + v_3^1 + 2v_4^2)^\pm$ are predicted to lie in the region studied. However, according to BYTe transitions in these bands are weaker than the ones listed in the table.

Table 6 gives a fuller comparison between the two calculations which covers all the vibrational band origins (VBOs) determined from Kitt Peak data both in this work and our previous study [12]; band origins for $(v_1 + v_2 + v_3^1)^-$ and $(2v_1v_4^1)^\pm$ are not given since they were not determined experimentally, *i.e.* there is no assignment to the P(1) transition in these bands, in our previous study. BYTe performs better than the *ab initio* study for VBOs in the lower

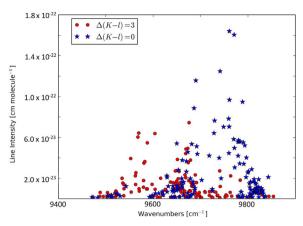

Fig. 5. Line assignments labelled by $\Delta(K - \ell)$.

energy region up to 8500 cm⁻¹. This observation is in line with the general finding that spectroscopically determined PESs only extrapolate reliably over a short range whereas a well-constructed *ab initio* PES can be used to make useful predictions for a wide range of VBOs.

Fig. 5 shows our assigned transitions classified according to whether $\Delta(K-\ell)=0$ or 3. Usually strong transitions in ammonia have $\Delta(K-\ell)=0$ and 'forbidden' transitions with $\Delta(K-l)>0$ are much weaker. While the strongest lines do indeed obey $\Delta(K-\ell)=0$, a significant proportion of the transitions obey $\Delta(K-\ell)=3$. We note that all approximate quantum numbers, *i.e.* vibrational labels, K and ℓ , were all taken directly from BYTe and cannot be considered to be definitive. It is therefore unclear if $\Delta(K-\ell)=3$ transitions are indeed stronger than might be expected or if this an artefact of the way BYTe assigns quantum numbers.

5. Conclusions

We have assigned 624 NH₃ lines from a near 1 μ m spectrum recorded in 1980 and obtained from the Kitt Peak archive. The whole spectrum contains 12,063 lines in the range 8978–10,349 cm⁻¹. Although some of these lines are not due to NH₃, indeed we removed 134 lines due to water, there are clearly many NH₃ lines that remain to be assigned. An updated version of the NH₃ MARVEL dataset is under construction [35] based on both the newly assigned Kitt Peak spectra. Finally, the Prague FTIR spectrum has been extended to higher frequency; we are currently analyzing the lines in this new spectra.

The line assignments presented here are the first made for NH₃ in this spectral region. Comparisons are made with the predictions of the BYTe line list [15] and a recent, high accuracy *ab initio* calculation [23]. While both reproduce the overall structure of the spectrum it is clear that further improvements are required for the spectrum to be reproduced accurately by variational nuclear motion calculations. Work has started using the MARVEL energy levels plus the new data from the Kitt Peak spectra presented here and previously [12] as the inputs to a fit for the NH₃ potential energy surface (PES). The *ab initio* PES of Polyansky et al. [23] provides a good starting point for this undertaking.
